ABSTRACT

Use of the Sunyaev-Zeldovich effect as a precise cosmological probe necessitates a realistic assessment of all possible contributions to Comptonization of the cosmic microwave background in clusters of galaxies. We have calculated the additional intensity change due to various possible populations of energetic electrons that have been proposed in order to account for measurements of intra-cluster radio, nonthermal X-ray and (possibly also) EUV emission. Our properly normalized estimates of (the highly model dependent value of) the predicted intensity change due to these electrons is well below $\sim 6\%$ and $\sim 35\%$ of the usual Sunyaev-Zeldovich effect due to electrons in the hot gas in Coma and A2199, respectively. These levels constitute high upper limits since they are based on energetic electron populations whose energy densities are *comparable* to those of the thermal gas. The main impact of nonthermal Comptonization is a shift of the crossover frequency (where the thermal effect vanishes) to higher values. Such a shift would have important consequences for our ability to measure cluster peculiar velocities from the kinematic component of the Sunyaev-Zeldovich effect.

1. Introduction

The Sunyaev-Zeldovich (S-Z) effect is a small intensity change that results from Compton scattering of the cosmic microwave background (CMB) radiation by electrons in the hot gas in clusters of galaxies (Zeldovich & Sunyaev 1969, Sunyaev & Zeldovich 1972). The effect constitutes a unique cluster and cosmological probe (for reviews, see Rephaeli 1995a, Birkinshaw 1999), whose great potential is beginning to be realized in recent years following the major observational progress in obtaining sensitive images of the effect by (mostly) interferometric arrays (Jones et al. 1993, Carlstrom et al. 2000, Udomprasert, Mason, & Readhead 2000, and the review by Carlstrom et al. 2001) and the increasingly more precise values of the Hubble constant (H_0) that have been deduced from S-Z and X-ray measurements. For example, a fit to data from 33 cluster distances yields $H_0 = 58 \text{ km s}^{-1} \text{ Mpc}^{-1}$ (in a flat cosmological model), with direct observational errors of $\pm 5\%$ (Carlstrom et al. 2001), but with a much larger level of systematic uncertainties. Among others, the latter include simplified modeling of the properties of the hot intracluster (IC) gas, and cluster morphology. These are the main limitations to the use of the S-Z effect as a precise cosmological probe, and as such give further motivation for in-depth studies of the cluster environment.

Energetic non-thermal (NT) electrons whose pressure is not negligible compared to the thermal gas pressure constitute an aspect of IC phenomena with possibly appreciable ramifications for precision S-Z measurements. The presence of significant energetic electron populations in many clusters has been known from measurements of diffuse IC radio emission, and recently also from NT X-ray emission in a few clusters (Rephaeli, Gruber & Blanco 1999, hereafter RGB, Fusco-Femiano et al. 1999, Kaastra et al. 1999, Gruber & Rephaeli 2002). NT electrons produce an additional degree of Comptonization which amounts to a small intensity change (ΔI_{nt}) that must be accounted for, particularly in the measurement of H_0 from the thermal component, and peculiar cluster velocities from the kinematic component of the S-Z effect. Relativistic generalizations (Rephaeli 1995b, Challinor & Lasenby 1998, Sazonov & Sunyaev 1998) of the original non-relativistic calculations of Sunyaev & Zeldovich (1972, 1980) have now been performed to a sufficiently high level of accuracy, including also terms of order τ^2 (Nozawa, Itoh, & Kohyama 1998, Itoh et al. 2000, Shimon & Rephaeli 2002), where τ is the Thomson optical depth of the cluster. In calculating the effect of multiple scatterings the finite size of the cluster has to be explicitly accounted for; this has been done in the Monte-Carlo simulations of Molnar & Birkinshaw (1999). The relativistic treatment provides the theoretical basis for calculation also of ΔI_{nt} .

CMB Comptonization by NT electrons was first assessed for conditions in lobes (McKinnon, Owen, & Eilek 1991) and cocoons (Yamada & Sugiyama 1999) of radio galaxies, with its possible use to measure their electron pressure. The effect of such electrons in clusters

was recently considered in some more detail (Blasi & Colafrancesco 1999, Ensslin & Kaiser 2000, Blasi, Olinto, & Stebbins 2000). Clearly, the higher the electron pressure, the higher is the degree of Comptonization induced by the electrons, and because models of NT electrons vary greatly in energy density, estimates of their impact on the CMB range from a negligible level, to a very substantial fraction of the thermal S-Z effect due to the hot gas. It is quite essential to study NT electron populations in order to *realistically* determine the spectral and spatial profiles of ΔI_{nt} in clusters in which extended radio emission has been measured. This may lead to ways by which their impact on S-Z work can be minimized, and eventually the Comptonization induced by NT electrons could perhaps even be used as a diagnostic tool of these electrons.

In this paper we perform an exact calculation of the degree of Comptonization predicted in a range of NT electron models that have been proposed to explain radio, EUV, and hard X-ray emission in clusters. Our estimates of ΔI_{nt} in Coma and A2199 are based on recent results on the electron populations in these clusters, and the main features of the resulting spectral change are contrasted with those of the thermal component of the S-Z effect.

2. Non-thermal Electron Populations

The main evidence for relativistic electrons and magnetic fields in clusters comes from measurements of extended IC regions of radio emission (in the frequency range $\sim 0.04 - 4$ GHz) with spectral indices and luminosities in the range $\sim 1 - 2$, and $10^{40.5} - 10^{42}$ erg/s ($H_0 = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$), respectively. Many of the radio emitting regions detected in over 30 clusters (Giovannini, Tordi, & Feretti 1999, Giovannini & Feretti 2000) are central, with sizes in the range $\sim 1 - 3$ Mpc. The energy range of the emitting electrons depends on the value of the mean, volume-averaged magnetic field, a quantity which is not known very well, but is likely to be in the range $\sim 0.1 - 1 \mu\text{G}$ (for a recent review, see Rephaeli 2001). The range of electron energies implied from these measurements is roughly $1 - 100$ GeV, but electrons with energies both below and above this range are also expected on theoretical grounds.

Relativistic electrons produce X-ray emission in a wide spectral range by Compton scattering off the CMB (Rephaeli 1979) and by NT bremsstrahlung. This emission has quite possibly been measured already in Coma (Rephaeli, Gruber & Blanco 1999, Fusco-Femiano et al. 1999), A2199 (Kaastra et al. 1999), A2256 (Molendi, De Grandi, & Fusco-Femiano 2000), and A2319 (Gruber & Rephaeli 2002) by the RXTE and BeppoSAX satellites. These were spectral measurements; the PCA, HEXTE (both aboard RXTE) and PDS (aboard BeppoSAX) experiments do not have the adequate spatial resolution. Thus, we have no spatial

information on NT electrons from X-ray measurements, and only rudimentary knowledge of the morphology of the radio emission (which, however, involves also the unknown spatial distribution of the magnetic field). Therefore, in order to avoid the need for introducing unknown parameters, we characterize electron populations in terms of the spectral distribution of their total number, ignoring their spatial profiles in the central ~ 1 Mpc region where they mostly reside.

Of the various proposed NT IC electron models (see, *e.g.*, Sarazin 1999) we focus here on those that have been contrasted with actual observational data, with the electron distribution appropriately normalized by the determination of both their total number and the power-law index, q . Some of the proposed electron models were motivated by the presumption that NT X-ray emission could also originate from NT bremsstrahlung by energetic – though not necessarily highly relativistic – electrons, and by an attempt to account also for observed EUV emission from a few clusters. This emission is said to be NT (*e.g.*, Sarazin & Lieu 1998, Bowyer et al. 1999), possibly by a population of low energy electrons. The full electron distribution could be described either as a sum of two separate parts (thermal plus NT), or by a ‘super Maxwellian’, consisting of a truncated Maxwellian with a power law tail (Blasi, Olinto, & Stebbins 2000) ‘sawn’ together at a given energy (*e.g.*, $\sim 3kT_e$, where T_e is the electron [and gas] temperature). We consider here four specific models whose parameters in Coma and A2199 have been determined from radio, EUV, and NT X-ray measurements.

The simplest model for the electron momentum distribution is a power-law over a sufficiently wide range so as to explain both the observed radio and possibly Compton-produced X-ray emission. We express the electron spectrum in terms of the (differential) number, $N(p)$, per unit dimensionless momentum, $p = \beta\gamma$, where γ and β are the Lorentz factor and dimensionless velocity, $\beta = v/c$, respectively,

$$N(p) = Ap^{-q}, \quad p_1 \leq p \leq p_2$$

$$A = \frac{N_{12}(q-1)}{p_1^{-(q-1)} - p_2^{-(q-1)}}. \quad (1)$$

The limiting momenta p_1 and p_2 are the lower and higher values of p that correspond to the *observed radio frequency range*, and N_{12} is the total number of electrons with energies in this specific interval, $[p_1, p_2]$. Details of such a model were worked out long ago (Rephaeli 1977, 1979) and will not be repeated here. Suffice it to say that the *full* momentum range is substantially uncertain, especially its low end which is of particular relevance to our discussion here.

A simple way to obtain the lower energy extension of the above distribution is to assume that steady state is attained, whereby electrons are continually accelerated to compensate

for radiative energy losses – defined here in terms of dp/dt – and a population of lower energy electrons is built up. The latter can be determined by taking into account the dominant rate of energy loss at energies well below ~ 150 MeV, electronic (Coulomb) excitations, given by (Rephaeli 1979)

$$b_{ee} = 1.2 \times 10^{-12} n_e \left[1.0 + \frac{\ln \left(\sqrt{1 + p^2/n_e} \right)}{75} \right] \text{ s}^{-1}, \quad (2)$$

where n_e is the (thermal) electron number density. At higher energies Compton-synchrotron losses dominate; these occur at a combined rate (*e.g.*, Rephaeli 1979)

$$b_{cs} = 1.37 \times 10^{-20} [(1+z)^4 + 9.5 \times 10^{-2} (B/1\mu\text{G})^2] \text{ s}^{-1}, \quad (3)$$

where z is the cluster redshift, and B is the mean, volume-averaged value of the magnetic field. The steady state solution is then (Rephaeli 1979)

$$\begin{aligned} N_I(p) &= \frac{Ab_{cs}}{b(p)} (1+p^2)^{-\frac{(q-2)}{2}} & (p_1 \leq p \leq p_2) \\ &= \frac{Ab_{cs}}{b(p)} (1+p_1^2)^{-\frac{(q-2)}{2}} & (p \leq p_1), \end{aligned} \quad (4)$$

where $b \equiv dp/dt = b_{ee} + b_{cs} (1+p^2)$. Clearly, the observed radio frequency range implies that $p_1 \gg 1$. (Note that another possible energy loss mechanism is scattering by Alfvén waves, which the electrons themselves can excite if their spatial distribution is somewhat anisotropic. Because of the substantial uncertainty in estimating this loss mechanism [*e.g.*, Rephaeli 1979] it will not be considered here.) Parameters of this model were determined from RXTE measurements of the Coma cluster, assuming the emission is from Compton scattering of relativistic electrons off the CMB (Rephaeli, Gruber, & Blanco 1999), and from BeppoSAX measurements of A2199 (Kaastra et al. 1999). This appropriately extended electron population which has a power-law form at low and high energies, but with indices whose values differ by unity, is our first model. The parameters of all the models considered here are given in Table 1.

Two other forms for $N(p)$ are discussed by Sarazin & Kempner (2000). In the first model electrons are accelerated to relativistic energies by shell-type supernova remnants (Baring et al. 1999). When the back reaction of the accelerating electrons on the shock structure is taken into account, then this presumably leads to a modified power-law form at small momenta, resulting in the following distribution,

$$N_{II}(p) = \frac{N_0 p^{-2}}{1 + p_c^2} \left[1 + \left(\frac{p_c}{p} \right)^2 \right]. \quad (5)$$

Cluster	Model	Model details	N_0	N_{nt}^{tot}	$N_{nt}^{tot}/N_{th}^{tot}$
Coma					
	I	Extended power law	2.275×10^{72}	1.09×10^{65}	4.70×10^{-7}
	II	Shock accelerated	4.270×10^{67}	2.98×10^{68}	1.28×10^{-3}
	III	Cooling electrons	5.238×10^{62}	3.13×10^{65}	1.35×10^{-6}
	IV	Simple power law $q=3.68$	8.970×10^{68}	9.27×10^{69}	0.04
A2199					
	I	Extended power law	2.306×10^{68}	1.66×10^{64}	2.10×10^{-7}
	II	Shock accelerated	4.240×10^{67}	6.22×10^{68}	7.90×10^{-3}
	III	Cooling electrons	5.238×10^{62}	3.13×10^{65}	3.95×10^{-6}
	IV	Power law $q=3.33$	5.420×10^{68}	6.47×10^{69}	0.082

Table 1: Models for NT electrons in the Coma and A2199 clusters.

We assume $p_c = 1$ in normalizing the model. Explicit account of Coulomb losses yields the third distribution

$$N_{III}(p) = \frac{2N_0 p^2}{1 + p^2}. \quad (6)$$

N_0 is derived from comparison of the models with observations and assuming that the hard X-ray emission mechanism is NT bremsstrahlung. The electron distribution in Equation (6) has an upper momentum cutoff at $p = 300$.

Sarazin & Kempner (2000) also propose a simple power law model which extends to lower energies *with no change in the index*. This is the fourth (IV) model explored here. The observationally deduced parameters for the above four models are listed in Table 1; in these models, the lower momentum cutoff is $p_1 = \sqrt{(1 + 3\Theta)^2 - 1}$, where $\Theta = kT_e/mc^2$.

3. Comptonization

A detailed description of the Comptonized spectrum resulting from scattering of the CMB by a thermal, non-relativistic population of electrons was given by Sunyaev & Zeldovich (1972, 1980). A more accurate treatment of the process requires relativistic generalization due to the rapid motion of electrons in the hot ($kT_e \leq 15$ keV) IC gas, as has been shown explicitly by Rephaeli (1995a). A fully relativistic treatment (but still in the Thomson limit, and with electron recoil and induced scattering safely ignored) is obviously required in order to calculate the Comptonized spectrum resulting from scattering of the radiation by a NT

energetic electron population. We use the approach adopted in the latter paper (see also Rephaeli & Yankovitch 1997).

The probability of scattering of an incoming photon moving originally in the direction specified by $\mu_0 = \cos \theta_0$, to the direction $\mu'_0 = \cos \theta'_0$, is (Chandrasekhar 1950)

$$f(\mu_0, \mu'_0) = \frac{3}{8} \left[1 + \mu_0^2 \mu'^2_0 + \frac{1}{2} (1 - \mu_0^2) (1 - \mu'^2_0) \right], \quad (7)$$

where the subscript 0 denotes quantities in the electron rest frame. The logarithmic frequency shift in the scattering is

$$s \equiv \ln(\nu'/\nu) = \ln \left(\frac{1 + \beta \mu'_0}{1 + \beta \mu_0} \right), \quad (8)$$

where β is the dimensionless electron velocity in the CMB frame. The probability for scattering is conveniently written in terms of the variables β and $t = e^s$ (Wright 1979),

$$\mathcal{P}(s, \beta) = \frac{1}{2\gamma^4 \beta} \int_{\mu_1}^{\mu_2} \frac{e^s f(\mu_0, \mu'_0)}{(1 + \beta \mu_0)^2} d\mu_0, \quad (9)$$

where μ_1 and μ_2 are given by

$$\mu_1 = \begin{cases} \frac{e^{-s}(1-\beta)-1}{\beta} & s \leq 0 \\ -1 & s \geq 0 \end{cases} \quad (10)$$

$$\mu_2 = \begin{cases} 1 & s \leq 0 \\ \frac{e^{-s}(1+\beta)-1}{\beta} & s \geq 0 \end{cases}. \quad (11)$$

Integration over μ_0 in Equation (9) yields

$$\begin{aligned} \mathcal{P}(t, p) &= -\frac{3|1-t|}{32p^6 t} [1 + (10 + 8p^2 + 4p^4)t + t^2] \\ &+ \frac{3(1+t)}{8p^5} \left[\frac{3 + 3p^2 + p^4}{\sqrt{1+p^2}} - \frac{3 + 2p^2}{2p} (2 \sinh^{-1}(p) - |\ln(t)|) \right], \end{aligned} \quad (12)$$

where

$$|\ln(t)| \leq 2 \sinh^{-1}(p). \quad (13)$$

Compton scattering results in a frequency shift, $x \rightarrow x'$, where x is the dimensionless frequency $x = h\nu/kT$, and T is the CMB temperature. The corresponding change of the

photon occupation number through a pathlength along the cluster, $\Delta n(x)$, is obtained by integrations over the scattering probability and electron momentum distributions,

$$\Delta n(x) = \tau \int_{p_1}^{p_2} \int_{t_{min}}^{t_{max}} dp dt \frac{N(p)}{N_{tot}} \mathcal{P}(t, p) \left(\frac{1}{e^{xt} - 1} - \frac{1}{e^x - 1} \right), \quad (14)$$

where τ is the optical depth of the cluster to Compton scattering, and N_{tot} is the total number of electrons in the cluster. The measured quantity is the change in intensity, $\Delta I(x)/i_0 = x^3 \Delta n(x)$, where $i_0 = 2(kT)^3/(hc)^2$. We use the latter equation to calculate the additional intensity change induced by energetic electrons, $\Delta I_{nt}(x)$, in the electron models described in the previous section, with parameter values sampling the observationally deduced ranges, as specified in Table 1 for all the four electron models.

If Comptonization by NT electrons is not taken into account it could affect the observationally deduced value of the crossover frequency, x_0 , defined as the frequency at which the *purely thermal* effect vanishes. The exact value of x_0 has practical significance, since observations near this frequency are optimal for the determination of cluster peculiar velocities (Rephaeli & Lahav 1991) from measurements of the kinematic component of the S-Z effect. We have calculated the modified value of the frequency where now the *sum* of the thermal and NT intensity changes vanishes. For this we used the analytic expression of Nozawa, Itoh, & Kohyama(1998) for the thermal and kinematic components of the S-Z effect, and computed x_0 using the measured values of the temperatures in Coma and A2199.

4. Results

The impact of each of the above four NT electron models depends very much on the total number of these electrons as determined by radio, NT EUV and X-ray emission. The thermal gas parameters are based on X-ray measurements. For Coma, recent XMM measurements yield $kT_e = 8.2 \pm 0.4$ keV for the gas temperature (Arnaud et al. 2001), and (since quantitative results for the gas density profile from either XMM or *Chandra* are not yet available) we have taken the ROSAT deduced values (Mohr, Mathiesen, & Evrard 1999), $n_{e0} \simeq (3.12 \pm 0.04) \times 10^{-3} \text{ cm}^{-3}$, $r_c = 0.366$ Mpc, and $\beta_n \simeq 0.705$, for the central electron density, core radius, and index in the expression for (the commonly used) density profile, $n_e(r) = n_{e0}(1 + r^2/r_c^2)^{-3\beta_n/2}$, respectively. The corresponding values in A2199 are $kT_e = 4.7$ keV, central electron density $n_{e0} = 7.21 \times 10^{-3} \text{ cm}^{-3}$, $r_c = 0.196$ Mpc, and $\beta_n = 0.78$ (Kaastra et al. 1999). These values are based on $H_0 = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$.

Clearly, most of the intensity change $\Delta I_{nt}(x)$ is due to the more numerous low energy electrons. More specifically, a typical CMB photon has dimensionless frequency $\bar{x} = 2.701$,

and the scattered photon frequency is on average

$$\frac{\bar{x}'}{x} = 1 + \frac{4}{3}p^2. \quad (15)$$

The observationally relevant range of values of x is at most $x \leq 20$, and since the (the 68% likelihood) interval of rms values of x' , $\Delta x' \simeq x\sqrt{2p^2/3 + 46p^4/45}$, is very wide for $p > 1$, it follows that electrons with momenta much larger than at most a few tens are largely irrelevant for boosting photons to frequencies such that $x \leq 20$. (Obviously, *all* electrons contribute to the value of the Thomson optical depth and the decrement on the Rayleigh-Jeans side.)

We have calculated $\Delta I_{nt}(x)/i_0$ and total electron energies in the extended power-law model described by equation (4), using the observationally deduced model parameters in Coma and A2199. We emphasize that the basic model is a power law at high energies (≥ 1 GeV) with the index determined from radio measurements. The distribution is then appropriately extended to lower energies (by taking electronic excitations losses into account) resulting in a change in the value of the index at low energies. The power law indices and overall normalizations were taken from Rephaeli, Gruber & Blanco (1999) for Coma, and Kaastra et al. (1999) for A2199. Based on these parameters, the deduced values of $\Delta I_{nt}(x)/i_0$ are very small in comparison with the magnitude of the thermal S-Z effect in these clusters as predicted from the measured values of the gas temperature and density. In Coma the S-Z effect was actually measured by Herbig et al. (1995) using the OVRO 5.5 m telescope, and more recently by De Petris et al. (2002) using the MITO telescope. In the former paper the temperature change in the center of Coma was reported to be $\Delta T = -505 \pm 92 \mu\text{K}$ at 32 GHz ($x \simeq 0.56$), a value which is consistent with that predicted based on the X-ray deduced parameters. A somewhat lower value was deduced by De Petris et al. (2002). Our calculated values of $\Delta I_{nt}(x)/i_0$ due to NT electrons are smaller than 0.001% of the predicted thermal effect in Coma and A2199. Clearly, the implied shift in the value of the crossover frequency is also negligible. The very small impact of NT electrons in this model is not surprising given the relatively low energy content of these electrons, $\sim 0.8\%$ of the thermal electron energy in Coma and A2199.

Next we calculated the degree of Comptonization in the shock accelerated and cooling electrons models (II and III) described in equations (5) and (6). We have normalized these models to match the observed EUV emission, at a luminosity level of roughly $5 \times 10^{43} \text{ erg s}^{-1}$ over the band 0.065-0.245 keV in both Coma and A2199. In the shock accelerated electron model the calculated levels of $\Delta I_{nt}(x)$ are $< 0.5\%$ and $\leq 3\%$ of the corresponding intensity change due to thermal electrons, and the shift in the value of the crossover frequency is also quite small. Calculated values of the energy in NT electrons in this model are $\sim 3\%$ and 13%-16% (for $p_c = 0.3 - 1.0$) of the energy in thermal electrons in Coma and A2199,

respectively. In the cooling electron model, the degree of NT Comptonization is negligible, less than 0.003% of the magnitude of the thermal S-Z effect in both Coma and A2199. This is mainly due to the small number of NT electrons in this model, $\sim 0.1\%$ of that in the shock accelerated electron model. The NT electron energy constitutes 0.9% and 4.2% of the electron thermal energy in the two clusters. Our calculated quantities are listed in Table 2. The first column is the cluster name (or Abell number), the second is the model number, third is the ratio of (total) energy in NT to energy in thermal electrons. In the fourth column we list the net energy deposition rate (in keV/Gyr) by NT electrons, and in the fifth the value of the crossover frequency; values of the error in the peculiar velocity and the ratio $\Delta I_{nt}(x)/\Delta I$ are listed in last two columns.

Cluster	Model	E_{nt}/E_{th} %	dE/dt (keV/Gyr)	x_{nt}	$\Delta v >$ (km/sec)	$\Delta I_{nt}/\Delta I$ %
Coma						
	Thermal			3.9000		
	I	0.79	−0.06	3.9000	-	1.4×10^{-4}
	II	3.18	10.80	3.9020	-	0.41
	III	0.90	−0.04	3.9000	-	4.7×10^{-4}
	IV	21.59	296.86	3.9216	-110	6.8
A2199						
	Thermal			3.8700		
	I	0.74	−0.15	3.8701	-	1.2×10^{-4}
	II	15.87	58.87	3.8803	-	2.97
	III	4.23	−0.06	3.8702	-	2.5×10^{-3}
	IV	64.17	626.39	3.9385	-210	34.5

Table 2: The impact of the four energetic electron models (see the text for definitions of the listed quantities).

The much higher NT electron energy content in the single power law (model IV) suggested by Sarazin & Kempner (2000), $\sim 20\% - 22\%$ (for $q = 2.92 - 3.68$) in Coma, and $\sim 64\% - 184\%$ (for $q = 2.2 - 3.33$) in A2199, result in substantial degrees of additional Comptonization. Using values of the parameters as deduced by Sarazin & Kempner (2000), listed in Table 1, we calculate the change of intensity, $\Delta I_{nt}(x)/i_0$, shown in Figure 1, and listed in Table 2. It is clear from this figure that $\Delta I_{nt}(x)$ can reach an appreciable fraction of $\Delta I(x)$. For example, near the peak of the Comptonized Planckian, at $x \sim 6.5$, $\Delta I_{nt}/\Delta I$ is $\leq 13\%$ and $\leq 35\%$ for Coma and A2199, respectively. The implied shift in the value of the crossover frequency in this model, ~ 2 GHz in Coma, and ≥ 4 GHz in A2199, would also

be observationally relevant. Such a systematic shift would introduce an error in the deduced value of the peculiar velocity. The implied error (which does not depend on the velocity, if the very small quadratic dependence of $\Delta I(x)$ on the velocity is ignored) amounts to ~ 110 km/s for Coma ($q = 2.92 - 3.68$), and ~ 210 km/s ($q = 3.33$) and 320 km/s ($q = 2.2$) for A2199 (values lower than 100 km/s are not shown in Table 2).

Fig. 1.— The spectrum of the additional Comptonization due to energetic electrons in the models proposed by Sarazin & Kempner (2000) for the Coma (left panel) and A2199 (right panel).

Finally, we have calculated the heating rate of the hot gas by the NT electrons through Coulomb interactions (Rephaeli 1979, Rephaeli & Silk 1995) in the four models considered in this paper. Energy deposition rates into the gas were estimated by taking a mean gas density in the central 1 Mpc region of Coma and A2199. Subtraction of the observed cooling rate due to thermal bremsstrahlung (X-ray) emission then yields the net rate of temperature change. Values of the latter quantity (in keV/Gyr) are listed in Table 2.

5. Discussion

We have briefly discussed models for NT energetic electrons and their predicted effect on the CMB based on parameters that were deduced from radio, EUV, and X-ray measurements of Coma and A2199. Our immediate objective has been the exact calculation of the additional degree of Comptonization due to these electrons, and its possibly relevant observational consequences. Only electron models that have direct observational motivation were considered. Since all these models have basically a power-law form, it is clear that their impact on the CMB is largely due to the more abundant lower energy electrons (except for

the cooling electrons model). However, the interpretation of the EUV and X-ray emissions as NT bremsstrahlung and Compton scattering are not secure, so there is considerable uncertainty in quantifying electron densities. Moreover, since low energy electrons lose energy mostly by non-radiative coupling to the thermal gas, the uncertainty in the estimation of their density is particularly substantial. Only the presence of relativistic electrons is well established from measurements of extended regions of radio emission in many clusters (including Coma, but not A2199). Clearly, radio measurements yield the electron density only if we have an independent estimate of the mean, volume-averaged value of the magnetic field in the emitting region. Estimates of the mean IC field are few and uncertain (Newman, Newman & Rephaeli 2002).

Due to the lack of detailed information on IC energetic electron populations, relevant theoretical considerations are of particular interest. First, since it is virtually always the case that particle acceleration mechanisms tap only a small fraction of the energy at the source, energy density in NT electrons is likely to be only a small fraction of the gas (which is a significant mass component of clusters) thermal energy density. Realistically, therefore, the thermal energy density in clusters is expected to set an absolute upper limit to the energy density in NT electrons, a limit which is very unlikely to be reached. Second, the energetic electron population is linked to the gas mainly by Coulomb coupling that results in energy transfer from energetic electrons (and protons) to the gas. This coupling and the resulting heating set stringent constraints on the attainment of steady state in general, and the density of low energy NT electron models in particular.

We have calculated the ratio of total energy in NT electrons to that in thermal electrons in the four energetic electron models considered in this paper; for the first three models the calculated values (in Table 2) are low. For the power law model of Sarazin & Kempner (2000), the corresponding values are very high ($\sim 22\%$ in Coma, and $\geq 64\%$ in A2199) and quite unrealistic. Such large energy contents would also imply a high rate of energy transfer to the gas, and heating at a rate higher than the rate of cooling by emission of thermal radiation. This without even considering the additional heating by IC energetic protons (whose energy density in the Galaxy is higher than that of relativistic electrons).

In fact, the single power law model of Sarazin & Kempner (2000) is not only unappealing from an energetic point of view, but is also questionable on a more basic physical ground: As we have stated in Section 2 – based on the original work of Rephaeli (1979) – correct extrapolation of the relativistic electron energy spectrum to low (< 100 MeV) energies must account for electronic Coulomb excitations, the dominant energy loss mechanism at such energies for typical gas densities in the central regions of clusters. The very weak energy dependence of this mechanism (in contrast with the quadratic dependence of the

Compton-synchrotron energy loss rate) flattens the spectrum at low energies, resulting in a much smaller number of electrons than would have been predicted otherwise. We conclude that this model is non-viable; therefore, the high degree of implied Comptonization and appreciable shift in the value of x_0 that are predicted in this model are at best very high upper limits to the impact of NT electrons on measurements of the S-Z effect.

Our basic result in this paper is that exact calculation of the impact of realistically normalized models of NT electrons in Coma and A2199 yields levels of the degree of Comptonization by such electrons that are only a negligible fraction of the corresponding S-Z effect due to the hot IC gas. It is clear from our discussion that this result is generally valid since the energy density in NT electrons is not likely to be a significant fraction of the thermal energy density. In clusters with a significant NT electron population the added Comptonization due to these electrons would clearly constitute a source of confusion in the analysis of S-Z measurements. Since there are little or no differences in the spectral CMB signatures of thermal and NT electrons, high spatial resolution X-ray, S-Z and radio measurements of these clusters would be needed in order to minimize this confusion when (as expected) the spatial profiles of the two electron populations are found to be detectably different.
